Data recorded by the JADE experiment at the PETRA e^+e^- collider were used to measure distributions of new event shape observables. The distributions were compared with resummed QCD calculations ($\mathcal{O}(\alpha_s^2)$ +NLLA), and the strong coupling constant α_s was determined at $\sqrt{s} = 22, 35$ and 44 GeV. The results are in agreement with previous combined results of PETRA but have smaller uncertainties. Together with corresponding data from LEP, the energy dependence of α_s is significantly tested and is found to be in good agreement with the QCD expectation.

1. INTRODUCTION

Summaries of measurements of α_s from various processes and at different energy scales Q demonstrate [1] that the energy dependence of α_s is in good agreement with the prediction of Quantum Chromodynamics (QCD). High precision tests are provided by e^+e^- annihilation data which were collected between some GeV and nearly 200 GeV. Unfortunately, in the interesting intermediate energy region where α_s runs very quickly, the “best” value of α_s , 0.14 ± 0.2 [1], is a combined result at $\sqrt{s} = 35$ GeV based on measurements at PETRA that are affected by large theoretical uncertainties because only QCD predictions up to $\mathcal{O}(\alpha_s^2)$ were available for event shape observables.

Significant progress has been made in perturbative QCD calculations since 1992. Observables have been proposed for which perturbative predictions are extended beyond the next-to-leading-order through the inclusion of leading and next-to-leading logarithms [8] which are summed to all orders of α_s (NLLA). Further, the precise measurements of the hadronisation process have improved the modelling of hadronic final states with Monte Carlo programs.

It is desirable to apply these LEP-established developments consistently to lower energy data in order to improve quantitative studies of the running of $\alpha_s(Q)$ over large ranges of the energy scale Q , using identical experimental techniques

and theoretical calculations in order to minimise point-to-point systematic uncertainties. In the following, $\mathcal{O}(\alpha_s^2)$ +NLLA determinations of α_s using data from the JADE experiment at PETRA at $\sqrt{s} = 22, 35$, and 44 GeV are presented [2].

2. JADE DATA

The JADE detector [3] was one of the five experiments at the PETRA electron-positron accelerator. It has operated from 1979 until 1986 at centre-of-mass energies of $\sqrt{s} = 12$ to 46.7 GeV. The main components of the detector were the central jet chamber to measure charged particle tracks and the lead glass calorimeter to measure electromagnetic showers.

Multihadronic events were selected by the standard JADE selection cuts [3] which reduce the background from $\gamma\gamma$ and τ -pair events to less than 0.1% and 1%, respectively [4]. The final numbers of events which were retained for this analysis are listed in Table 1, together with the corresponding integrated luminosities. The physical results of previous publications by JADE can be very well reproduced [2].

Monte Carlo detector simulation corresponding to the JADE data were retrieved for 35 and 44 GeV. They were generated using the JETSET QCD shower event generator version 6.3 [6]. In general, there is good agreement of the detector simulation with data for all event shape distribu-

Table 1

Number of multihadronic events in JADE data and corresponding integrated luminosities.

year	$\sqrt{s}$ [GeV]	data	luminosity
1981	22	1404	2.4 pb^{-1}
1984/85	39.5-47.8	6158	80 pb^{-1}
1986	35	20926	40 pb^{-1}

tions studied here. The simulated data can thus be used to correct for detector effects in the measured data.

3. DETERMINATION OF α_s

3.1. Event shapes and jetrates

From the data samples, the event shape distributions of thrust T , the heavy jet mass M_H , the total and wide jet broadening B_T and B_W and the differential 2-jet event rate using the Durham jet finder y_{23} were determined (c.f. [2]). For the latter three observables, no experimental results have previously been presented at these energies.

3.2. Correction procedure

The event shape data were corrected for the limited acceptance and resolution of the detector and for initial state photon radiation effects by applying a bin-by-bin correction procedure. It turns out that there is an excellent agreement between the data and the model prediction at *hadron level* over the whole kinematic range of the observables even for those ones which were never tested at such low energies [2].

No detector simulation were available for the 22 GeV data. Therefore only the differential 2-jet rate was considered because it is known to depend to a lesser extend on detector effects. The 35 GeV correction was applied to the 22 GeV data since the correction factors for this observable were found to show no significant energy dependence [2].

In a second step, the data distributions were corrected for hadronisation effects by applying bin-by-bin correction factors derived from the ratio of the JETSET generated distributions before and after hadronisation. The data distributions, thus corrected to the *parton level*, can be compared directly to analytic QCD calculations.

Figure 1. Distributions for $1 - T$ and $M_H/\sqrt{s}$ at $\sqrt{s} = 35$ GeV corrected to parton level. The fits of the QCD predictions are overlaid and the fit ranges are indicated by the arrows.

3.3. $\mathcal{O}(\alpha_s^2)$ +NLLA predictions

The event shape observables used in the analysis are predicted in perturbative QCD by a combination of the $\mathcal{O}(\alpha_s^2)$ [7] and the NLLA [8] calculations. The $\mathcal{O}(\alpha_s^2)$ calculation yields an expression of the form

$$R_{\mathcal{O}(\alpha_s^2)}(y) = 1 + A(y) \left(\frac{\alpha_s^2}{2\pi} \right) + B(y) \left(\frac{\alpha_s^2}{2\pi} \right)^2,$$

where $R(y) = \int_0^y dy' 1/\sigma_0 \cdot d\sigma/dy'$ is the cumulative cross-section of an event shape observable y normalised to the lowest order Born cross-section σ_0 . The NLLA calculations give an expression for $R(y)$ in the form:

$$R_{\text{NLLA}}(y) = \left(1 + C_1 \left(\frac{\alpha_s^2}{2\pi} \right) + C_2 \left(\frac{\alpha_s^2}{2\pi} \right)^2 \right).$$

Figure 2. Distributions for B_T and B_W at $\sqrt{s} = 35$ GeV corrected to parton level. The fits of the QCD predictions are overlaid and the fit ranges are indicated by the arrows.

$$\cdot \exp \left[L g_1 \left(\frac{\alpha_s^2}{2\pi} L \right) + g_2 \left(\frac{\alpha_s^2}{2\pi} L \right) \right]$$

where $L = \ln(1/y)$. The functions g_1 and g_2 are given by the NLLA calculations. The coefficients C_1 and C_2 are known from the $\mathcal{O}(\alpha_s^2)$ matrix elements.

The strong coupling α_s was determined by χ^2 fits to the event shape distributions corrected to the *parton level*. For the sake of direct comparison with other published results this analysis closely followed the procedures described in [5]. The so-called $\ln(R)$ -matching scheme was chosen to merge the $\mathcal{O}(\alpha_s^2)$ with the NLLA calculations. The renormalisation scale factor, $x_\mu \equiv \mu/\sqrt{s}$, was set to $x_\mu = 1$ for the main result.

The fit ranges are determined by the requirements of moderate hadronisation uncertainties

Figure 3. Distributions for y_{23} at $\sqrt{s} = 22$ and 35 GeV corrected to parton level. The fits of the QCD predictions are overlaid and the fit ranges are indicated by the arrows.

within the fit ranges, good $\chi^2/\text{d.o.f.}$ and reasonably stable fits under changes of the range.

3.4. Systematics

To study systematic uncertainties [2] details of the event selection and of the correction procedure were modified. The impact of the hadronisation model of the JETSET generator was studied by varying several significant model parameters. Mass effects are estimated conservatively by excluding the b-quark from the correction procedure. Uncertainties due to contributions of unknown higher order corrections are estimated by the changes of α_s when varying the renormalisation scale factor x_μ in the range of 0.5 to 2.0. Any resulting deviation from the main result was considered as systematic error.

3.5. Results

As an example, the theoretical predictions for the observables $1 - T$, M_H , B_T and B_W at $\sqrt{s} = 35$ and y_{23} at $\sqrt{s} = 22$ and 35 GeV are presented in Figures 1 - 3 and superimposed on the corresponding measured distributions corrected to *parton level*. In general, resummed calculations (solid lines) give a good description of the observables over their entire range of values even at the low PETRA energies, while the $\mathcal{O}(\alpha_s^2)$ calculations (dashed lines) which are shown for comparison fail in describing the 2-jet region.

The values of α_s and the errors obtained at 35 and 44 GeV are shown in Figure 4 in comparison with the α_s values measured by OPAL at $\sqrt{s} = M_{Z^0}$ [5]. The values of α_s exhibit a similar scattering pattern at all energies. This demonstrates the strong correlation of the systematic uncertainties at JADE and OPAL.

The individual results of the five observables at each energy were combined [2] into a single value. The final results for α_s are

$$\alpha_s(44\text{GeV}) = 0.1372 \pm 0.0017(\text{stat.})^{+0.0101}_{-0.0069}(\text{syst.})$$

$$\alpha_s(35\text{GeV}) = 0.1434 \pm 0.0010(\text{stat.})^{+0.0112}_{-0.0065}(\text{syst.})$$

$$\alpha_s(22\text{GeV}) = 0.1608 \pm 0.0083(\text{stat.})^{+0.0137}_{-0.0058}(\text{syst.})$$

where the result at 22 GeV is based on y_{23} only. The main contributions to the systematic errors come from renormalisation scale uncertainties and mass effects which causes systematically higher values for α_s .

4. SUMMARY AND CONCLUSIONS

JADE data at $\sqrt{s} = 22, 35$ and 44 GeV were used to measure α_s simultaneously with old (T , M_H) and new (B_T , B_W , y_{23}) event shape observables. The corresponding $\mathcal{O}(\alpha_s^2)$ +NLLA predictions are in good agreement with the measured distributions corrected to parton level even at PETRA energies.

It can be pointed out that the present measurements of α_s are the most precise in this energy region of the e^+e^- continuum. The individual results are *consistent* with each other. The errors are dominated by effects of missing higher orders in the QCD calculations.

Figure 4. Values of $\alpha_s(35 \text{ GeV})$ and $\alpha_s(44 \text{ GeV})$ derived from $\mathcal{O}(\alpha_s)$ +NLLA fits to event shape distributions, compared with OPAL results. The experimental and statistical uncertainties are represented by the solid, the total error by the dashed error bars.

Evolving the measurements to $\sqrt{s} = M_{Z^0}$ the results obtained at 44, 35 and 22 GeV transform to a combined value of $\alpha_s(M_{Z^0}) = 0.122^{+0.008}_{-0.005}$ which is consistent with the direct measurement at $\sqrt{s} = M_{Z^0}$ by OPAL of $\alpha_s(M_{Z^0}) = 0.117^{+0.008}_{-0.006}$ [5], for the same subset of observables.

Similarities between the main detector components of JADE [3] and OPAL [9], as well as between this analysis and studies performed by OPAL [5,10] at $\sqrt{s} = 91.2, 133$, and 161 GeV, allow for a precision test of the energy dependence of α_s between $\sqrt{s} = 22$ -161 GeV. The α_s values from OPAL and from this analysis are shown in Figure 5. The result of a χ^2 fit of the $\mathcal{O}(\alpha_s^3)$ QCD prediction to the data is shown by the solid line corresponding to $\alpha_s(M_{Z^0}) = 0.1207 \pm 0.0012$ and $\chi^2/\text{d.o.f.} = 4.9/5$, taking into account only statistical and experimental uncertainties.

Figure 5. Values of α_s from $\mathcal{O}(\alpha_s^2)$ +NLLA fits at JADE and OPAL. The solid error bars are the statistical and experimental uncertainties, the dotted error bars are the total errors. The solid line and the shaded band represent a QCD-fit to the data and its statistical error, respectively.

A fit for the hypothesis $\alpha_s = \text{const.}$ gives a $\chi^2/\text{d.o.f.} = 101/5$ which has a vanishing probability. The energy dependence of α_s is therefore significantly demonstrated by the results from the combined JADE and OPAL data.

QUESTIONS

D. Dissertori, CERN:

Why did you use only the $\ln(R)$ -matching scheme? Typically a set of different matching schemes is used, and this in the end could increase your systematic error.

P.A.M. Fernández:

In order to compare the present measurements consistently with the results given by OPAL, I applied only the $\ln(R)$ -matching scheme because it is commonly used in OPAL analyses. It has turned out that this matching scheme gives the best description of data [5], and that the results from other matching schemes with comparable quality do not significantly differ from the standard results.

L. Trentadue, Parma:

Is the quality of the data sufficiently good that the hadronisation effects are small enough at low energies?

P.A.M. Fernández:

Of course, the hadronisation effects and its uncertainties get larger at lower energies, but they remain small enough to perform reasonable measurements within the fit ranges chosen in this analysis, even at $\sqrt{s} = 22$ GeV.

L. Trentadue, Parma:

It would be useful to consider the variable ‘energy-energy-correlation’ for which the analysis of PETRA data has been done at NLLA level in the early eighties.

P.A.M. Fernández:

I agree, but I focussed only on the standard set of observables which OPAL uses for α_s measurements at high energies, in order to provide comparable results over a large range of the e^+e^- continuum.
